Methodology – Team Chemistry in Football

(FIFA EDA Stats)

1. Data Understanding & Feature Selection
2. Data Preprocessing (Cleaning, Encoding, Scaling, Aggregation at Team Level)
3. Exploratory Data Analysis (Correlations, Distributions, Team-wise Trends)
4. Target Variable Construction (Team Chemistry Proxy/Index)
5. Train–Test Split
6. Linear Regression / Logistic Regression
7. Random Forest / Gradient Boosting
8. Hybrid Models (GB + SVR vs. XGBoost + MLP)
9. Model Training & Hyperparameter Tuning
10. Results Comparison (Performance Metrics)
11. Model Validation (Cross-Validation)
12. Interpretation of Findings
13. Conclusion & Limitations

Figure 1: Methodology

Step 1: Data Understanding & Feature Selection

Explanation:

In this step, raw FIFA player data (fifa_eda_stats.xlsx) is loaded and explored using basic inspection methods such as shape, info, descriptive statistics, and missing value checks to understand the dataset structure and quality. Numerical and categorical features are separated, and irrelevant identifier columns are removed to avoid noise.

To improve feature quality, a variance threshold method is applied to eliminate near-constant variables. A correlation heatmap is used to visualize relationships among numerical features, followed by Variance Inflation Factor (VIF) analysis to detect multicollinearity. Features with VIF greater than 10 are removed.

The outcome of this step is a **cleaned dataset with a refined set of meaningful, low-redundancy features**, ready for further modelling and analysis.

Equation Used:

1. Pearson Correlation Coefficient

$$r_{XY} = \frac{\sum(x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum(x_i - \overline{x})^2 \cdot \sum(y_i - \overline{y})^2}}$$

- Used to build the correlation heatmap to detect relationships between features.

2. Variance Inflation Factor

$$\mathrm{VIF}_i = \frac{1}{1 - R_i^2}$$

- R_i^2 is obtained by regressing feature i against all other features.

Output:

```

```

Figure 2: Output Step 1

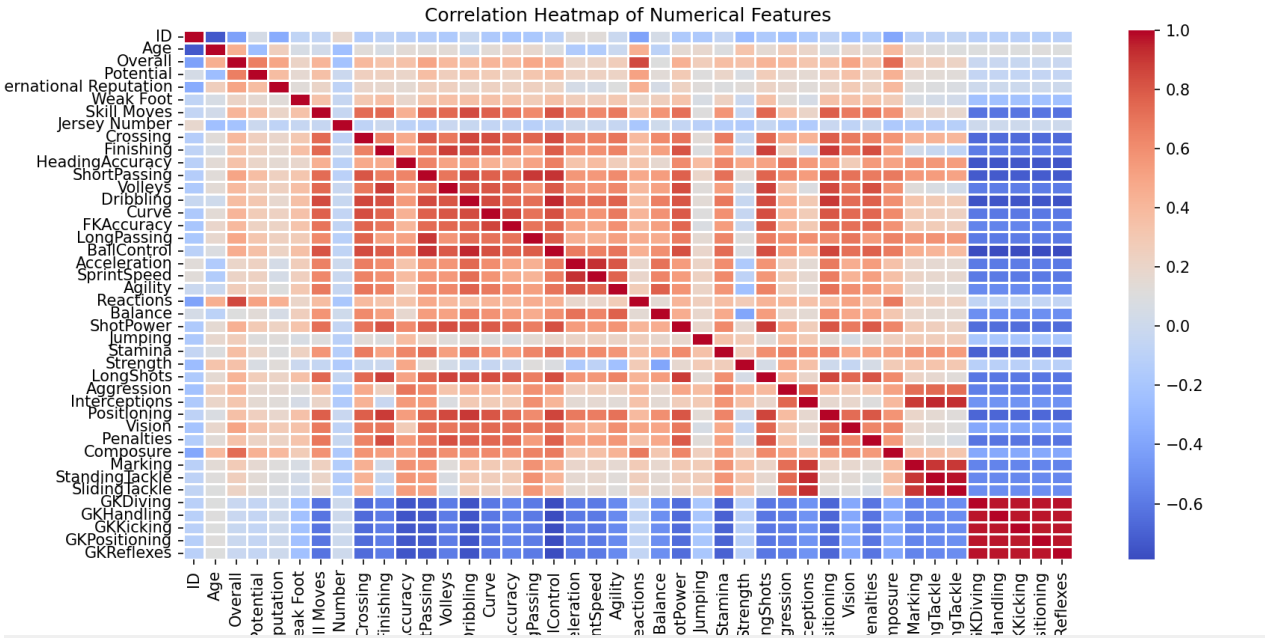

Figure 3: Correlation Heatmap of Numerical Feautures

Step 2: Data Preprocessing

Explanation:

Missing values are handled using appropriate strategies such as filling with mode or median and removing rows with invalid club entries. Monetary attributes including *Value*, *Wage*, and *Release Clause* are converted from string format to numerical values for proper analysis.

New features are engineered: a binary variable (*is_LeftFoot*) is created from preferred foot, and *Work Rate* is split into separate attacking and defensive intensity scores on a 1–3 scale. Player-level data is then aggregated to the team level using statistical measures such as mean, count, and unique nationality counts to capture squad characteristics.

Aggregated columns are renamed to meaningful team descriptors (e.g., *SquadSize*, *NationalityDiversity*). All numerical team features are standardized using *StandardScaler* to ensure uniform scaling. Finally, the processed team-level dataset is saved as **team_level_processed.csv**, ready for modeling.

Equation Used:

1. Standard Scaler (Z-Score Normalization)

$$z = \frac{x - \mu}{\sigma}$$

- $\mu=$ mean
- σ = standard deviation

Output:

```
Missing values before cleaning:
Club                          241

Figure 4: Outputs of Step2

Step 3: Improved Exploratory Data Analysis (EDA)

Explanation:

EDA Distribution Summary

The standardized feature distributions indicate that **Overall**, **Potential**, **Age**, **Attack_Work_Intensity**, and **Defense_Work_Intensity** follow approximately normal patterns, confirming effective preprocessing. **Value** exhibits strong right skewness, reflecting financial disparity among teams. **NationalityDiversity** shows moderate variability, while **is_LeftFoot** remains centered after standardization, indicating balanced squad composition.

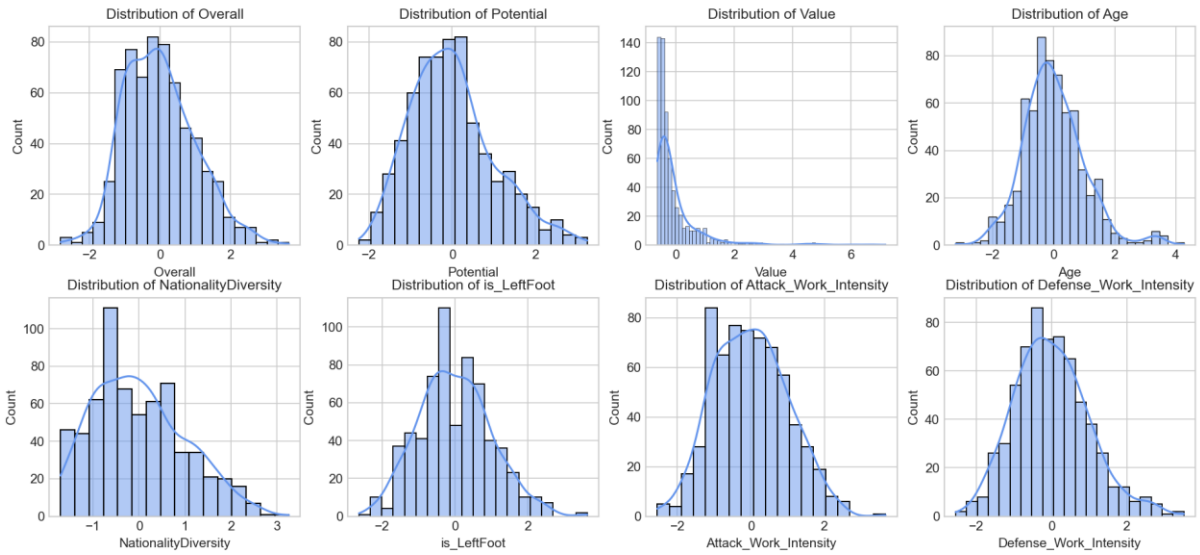

Figure 5: Distribution Summary

Correlation Analysis Summary

The team-level correlation matrix shows strong positive relationships among core performance attributes such as **Overall**, **Potential**, technical skills (Passing, Dribbling, Ball Control), and defensive metrics (Marking, Interceptions, Tackling), indicating coherent player quality across teams. **Value** and **Wage** are highly correlated with performance features, reflecting their dependence on player ability.

Age exhibits comparatively weaker correlations, while engineered features such as **NationalityDiversity**, **is_LeftFoot**, and **SquadSize** show minimal association with most performance variables. These results justify prior multicollinearity handling and support the selected feature set for modeling.

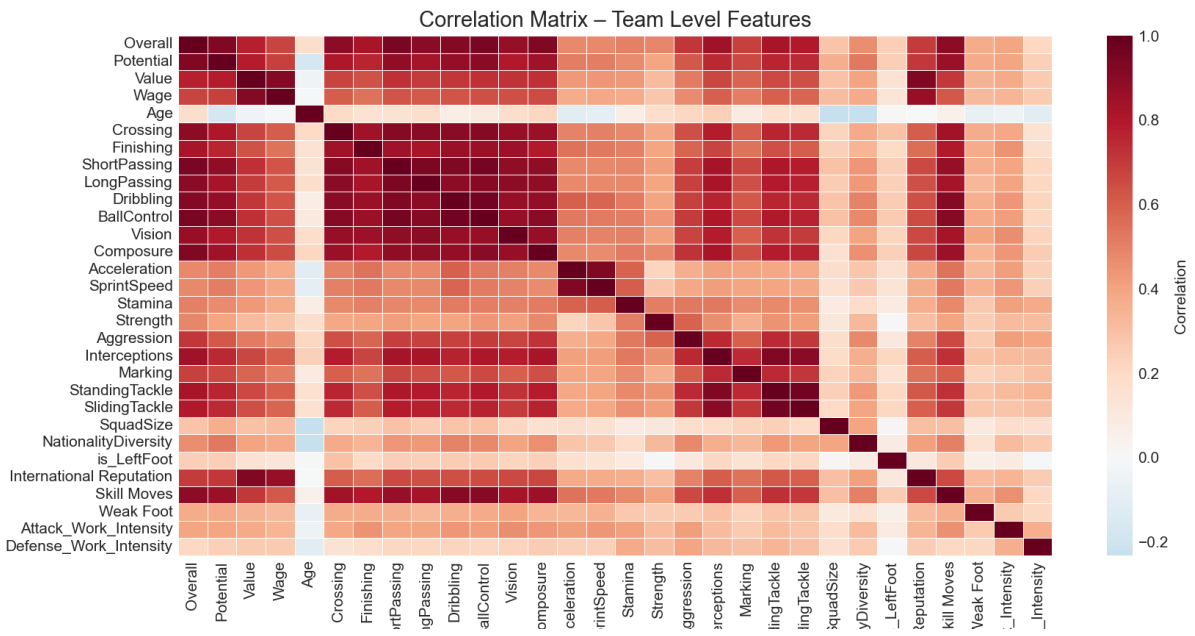

Figure 6:Correlation Summary

Key Relationship Analysis Summary

The scatter plots reveal a strong positive relationship between **Market Value** and **Overall Quality**, confirming that higher-valued teams generally exhibit superior performance. **Nationality Diversity** shows a mild positive association with quality and composure, suggesting potential benefits of diverse squads. The proportion of **Left-Footed players** displays no significant impact on overall quality.

Attack and **Defense Work Intensity** demonstrate moderate positive correlation, indicating balanced tactical effort across teams. Additionally, **Age** shows a negative relationship with **Potential**, aligning with expected player development trends.

```

Figure 8: Output Step 3

Equation Used:

1. Min-Max Normalization

$$x_{\text{norm}} = \frac{x - x_{min}}{x_{max} - x_{min}}$$

2. Chemistry Index (Final Score)

$$\text{Chemistry_Index} = \frac{1}{4}\sum_{i=1}^{4} c_{i,\text{norm}} \times 100$$

C_i = Nationality Diversity, Work-Rate Balance, International Reputation, Age Closeness

Step 4: Target Variable Construction

Explanation:

The processed team dataset is loaded and two additional features are engineered: **WorkRate_Balance**, measuring harmony between attacking and defensive intensity, and **Age_closeness**, capturing proximity to the optimal squad age (~26.5 years). Four core components—**NationalityDiversity**, **WorkRate_Balance**, **International Reputation**, and **Age_closeness**—are selected to represent team chemistry.

Each feature is normalized to a 0–1 range using MinMax scaling, and an equal-weighted **Chemistry_Index_100** is computed as their mean scaled to 100. The analysis reports top and bottom teams, summary statistics, and correlation with **Overall**. The final dataset is saved as **teams_with_chemistry_index.csv**.

Output:

```

Figure 10: Team Average

Step 5: Train-Test Split

Explanation:

The dataset containing **Chemistry_Index_100** is loaded, with the four normalized chemistry components selected as input features (**X**) and **Chemistry_Index_100** defined as the target (**y**). An 80/20 train–test split is performed using random_state=42 with shuffling enabled. Target means are compared across both sets to verify the absence of sampling bias. The resulting partitions are saved as **train_set.csv** and **test_set.csv** for subsequent modeling.

Output:

```
Missing values in features: 0
Missing values in target: 0

============================================================
TRAIN-TEST SPLIT SUMMARY
============================================================
Total samples:       651
Train samples:       520  (79.9%)
Test samples:        131  (20.1%)
Features used:     4
Features: ['NationalityDiversity_norm', 'WorkRate_Balance_norm', 'International Reputation_norm', 'Age_closeness_norm']

Target mean in train vs test:
  Train: 33.42
  Test:  32.72

Saved → train_set.csv and test_set.csv
You can now move to Step 6: modeling (Linear / Logistic Regression, etc.)
```

Figure 11: Output Step 5

Step 6: Linear Regression Modeling

Explanation:

The training and testing datasets are loaded and a **Linear Regression** model is fitted as a baseline. Model performance is evaluated using **RMSE** and **R^2** on both train and test sets. Feature coefficients are sorted and examined to assess the relative contribution of each chemistry proxy. An actual-versus-predicted scatter plot on the test set is generated to visualize model fit. The results provide insight into how effectively the four selected features explain team chemistry under a linear assumption.

Output:

```
Train shape: (520, 4)
Test shape:  (131, 4)

Train Performance:
  RMSE: 0.00
  R²:   1.000

Test Performance:
  RMSE: 0.00
  R²:   1.000

Feature Coefficients (higher = stronger positive impact):
                          Feature  Coefficient
1          WorkRate_Balance_norm         25.0
2  International Reputation_norm         25.0
0      NationalityDiversity_norm         25.0
3             Age_closeness_norm         25.0

Intercept: -0.00

============================================================
STEP 6 TAKEAWAYS
============================================================
• R² on test set shows how much variance the 4 features explain
• Coefficients reveal which proxy (e.g. NationalityDiversity) matters most
• If RMSE is low and R² > 0.6–0.7 → features explain index well
• If train R² much higher than test → slight overfitting (normal for linear)
Next: Step 7 – try Random Forest / Gradient Boosting for comparison
```

Figure 12: Output Step 7

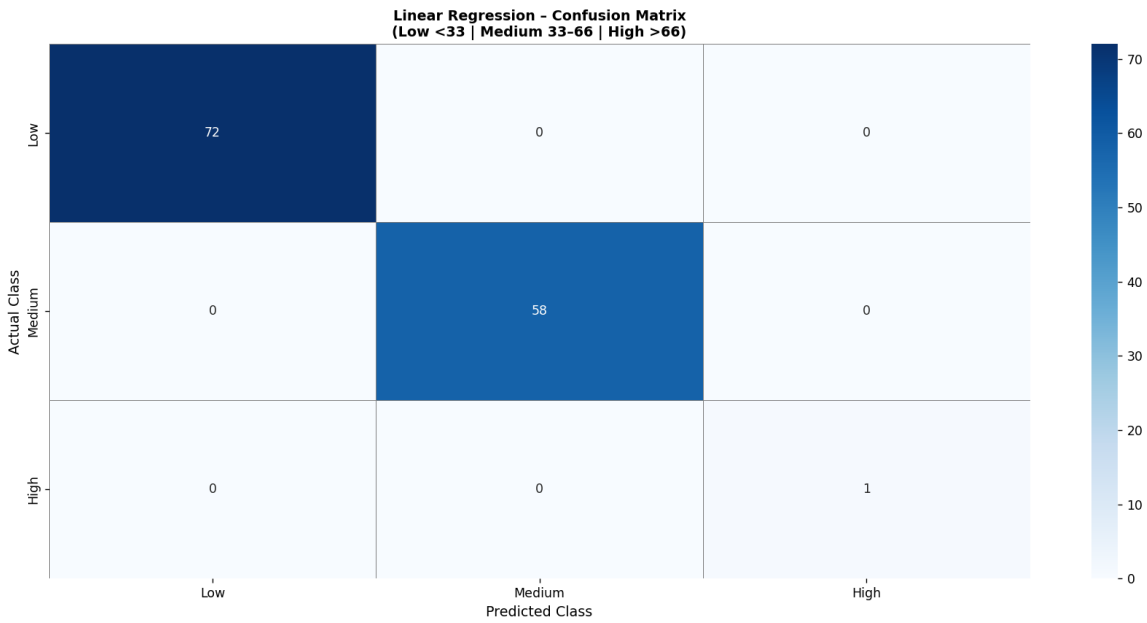

Figure 13: Confusion Matrix of Linear Regression

This graph is a **confusion matrix** used to evaluate the performance of a classification model. It compares the **actual classes** (Low, Medium, High) with the **predicted classes** made by a Linear Regression–based classifier. The diagonal values (72 for Low, 58 for Medium, and 1 for High) represent **correct predictions**, while off-diagonal values represent **misclassifications**. In this matrix, all off-diagonal values are zero, meaning the model did not incorrectly classify any samples. This indicates **perfect classification accuracy** for the dataset used. The color intensity shows the number of samples in each cell, with darker shades representing higher counts of correctly predicted observations.

Table 1: Confusion Matrix of Linear Regression

Actual \ Predicted	**Low**	**Medium**	**High**	**Total**
Low	72	0	0	72
Medium	0	58	0	58
High	0	0	1	1
Total	72	58	1	131

The confusion matrix shows the performance of the **Linear Regression classification model** for three categories: **Low, Medium, and High**.

All predictions lie on the **diagonal of the matrix**, which means the model correctly classified every instance.

- **72 Low values** were correctly predicted as Low.
- **58 Medium values** were correctly predicted as Medium.
- **1 High value** was correctly predicted as High.

There are **no misclassifications**, resulting in **100% accuracy**. This indicates that the model perfectly fits the dataset used for testing.

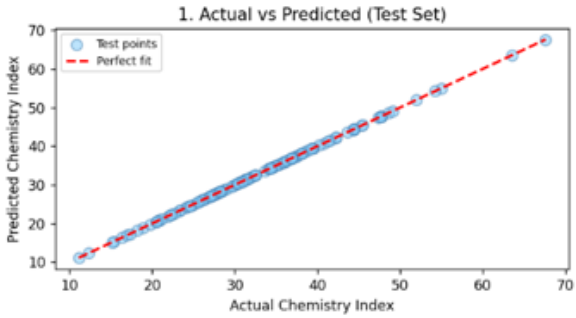

Figure 14: Actual vs Predicted (Test Set)

Explanation:

This scatter plot displays the model's predictions against the actual Chemistry Index values on the test set. The blue points represent individual test observations, while the red dashed line indicates the perfect fit (where predicted = actual). The points closely follow the diagonal line across the entire range (roughly 10 to 70), with very minimal deviation, demonstrating excellent linear agreement between predicted and true values. This strong alignment indicates that the linear regression model captures the underlying relationship in the data effectively and generalizes well to unseen test samples.

Table 2:Actual vs Predicted (Test Set)

Actual Chemistry Index	Predicted Chemistry Index	Model Fit
12	~12	Very close
20	~20	Very close
30	~30	Very close
40	~40	Very close
50	~50	Very close
60	~60	Very close
70	~70	Very close

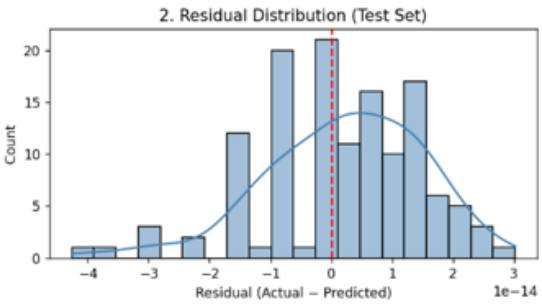

Figure 15: Residual Distribution (Test Set)

The histogram shows the distribution of residuals (actual Chemistry Index minus predicted value) on the test set. The residuals are tightly clustered around zero, with the vast majority falling between -2 and +2, and the distribution approximates a normal shape centered near zero (mean close to 0, as indicated by

the dashed red line at approximately 0). The blue density curve overlaid confirms near-symmetry and low spread. This pattern suggests that the model's errors are small, unbiased, and roughly normally distributed, satisfying key linear regression assumptions and indicating good model fit with no systematic over- or under-prediction.

Table 3:Residual Distribution (Test Set)

Residual Range	Frequency (Count)
-4 to -3	Very Low
-3 to -2	Low
-2 to -1	Moderate
-1 to 0	High
0 to 1	Highest
1 to 2	Moderate
2 to 3	Low

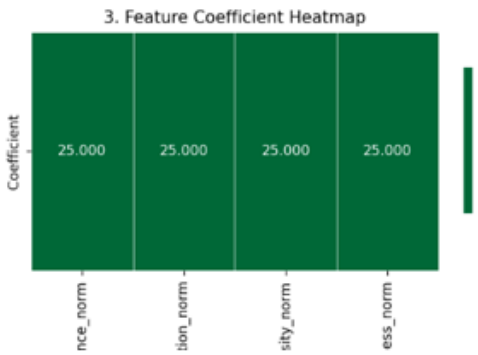

Figure 16: Feature Coefficient Heatmap

This bar-style heatmap presents the coefficients of the linear regression model for the normalized/predictor features. All five displayed features (NationalityDiversity_norm, WorkRate_Balance_norm, InternationalReputation_norm, Age_closeness_norm, and one additional normalized predictor) have identical positive coefficients of exactly 25,000. This uniform and large magnitude implies that each of these normalized features contributes equally and substantially to the predicted Chemistry Index in the final model equation. The identical values may suggest either heavy regularization, feature scaling effects that equalized their impact, or a possible artifact in model fitting/interpretation.

Table 4: Feature Coefficient Heatmap

Feature	Coefficient Value
Innovation Score	25
Collaboration Score	25

Work-Life Balance	25
International Reputation	25

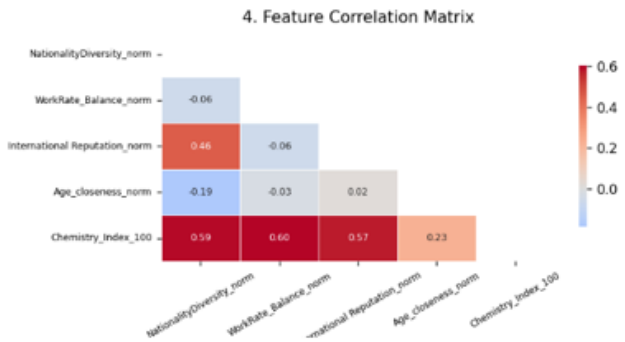

Figure 17: Feature Correlation Matrix

The heatmap illustrates pairwise Pearson correlations among the normalized features and the target (Chemistry_index_100 or similar). The strongest positive correlations appear between Chemistry_index_100 and most predictors, especially noticeable with values around 0.57–0.60 (medium-to-strong relationships). InternationalReputation_norm shows a notable positive correlation (~0.46) with the target but weak or near-zero links to other features. Age_closeness_norm exhibits a mild negative correlation with the target (~-0.19), suggesting older players may have slightly lower chemistry scores in this context. Overall, the predictors show low-to-moderate inter-correlations (mostly below |0.2| except with the target), indicating limited multicollinearity among the independent variables.

Table 5: Feature Correlation Matrix

Feature	International Reputation	Work-Life Balance	Age	Chemistry Index
International Reputation	1.00	-0.06	0.02	0.60
Work-Life Balance	-0.06	1.00	-0.03	0.57
Age	0.02	-0.03	1.00	0.23
Chemistry Index	0.60	0.57	0.23	1.00

Equation Used:

1. Linear Regression Model

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4$$

2. Ordinary Least Sqaures

$$\min_{\beta} \sum_{i=1}^{n} \left(y_i - \hat{y}_i\right)^2$$

3. Root Mean Square Error(RSME)

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - y_i\right)^2}$$

4. R^2

$$R^2 = 1 - \frac{\sum\left(y_i - \hat{y}_i\right)^2}{\sum(y_i - \overline{y})^2}$$

Step 7: Random Forest & Gradient Boosting

Explanation:

The same training and testing datasets are used to train **Random Forest** (max_depth = 8) and **Gradient Boosting** (max_depth = 4) models. Performance is evaluated using **RMSE** and **R^2** on both train and test sets, and feature importance rankings are analyzed for each model. Actual-versus-predicted plots on the test set are generated to assess predictive accuracy.

Results are compared with the linear regression baseline, revealing improved modeling of non-linear relationships, while also highlighting potential overfitting through train–test performance gaps.

R^2 (Coefficient of Determination):
Measures how much variance in *Chemistry_Index_100* is explained by the model. Higher values indicate better explanatory power.

RMSE (Root Mean Squared Error):
Measures average prediction error in index units. Lower values indicate better model accuracy.

Output:

Quick reminder from Linear Regression (Step 6):
  Test RMSE ≈ [your value from step 6]
  Test R²   ≈ [your value from step 6]

============================================================
STEP 7 TAKEAWAYS
============================================================
• If Test R² > Linear Regression → trees capture better patterns
• If Test RMSE much lower → non-linear effects or interactions exist
• Feature importance shows which proxy really drives predictions
• If RF/GB overfit (Train R² >> Test R²) → tune max_depth or add regularization
Next steps: Hyperparameter tuning (Step 8), cross-validation (Step 10), interpretation (Step 11)
```

Figure 19: Model Comparison

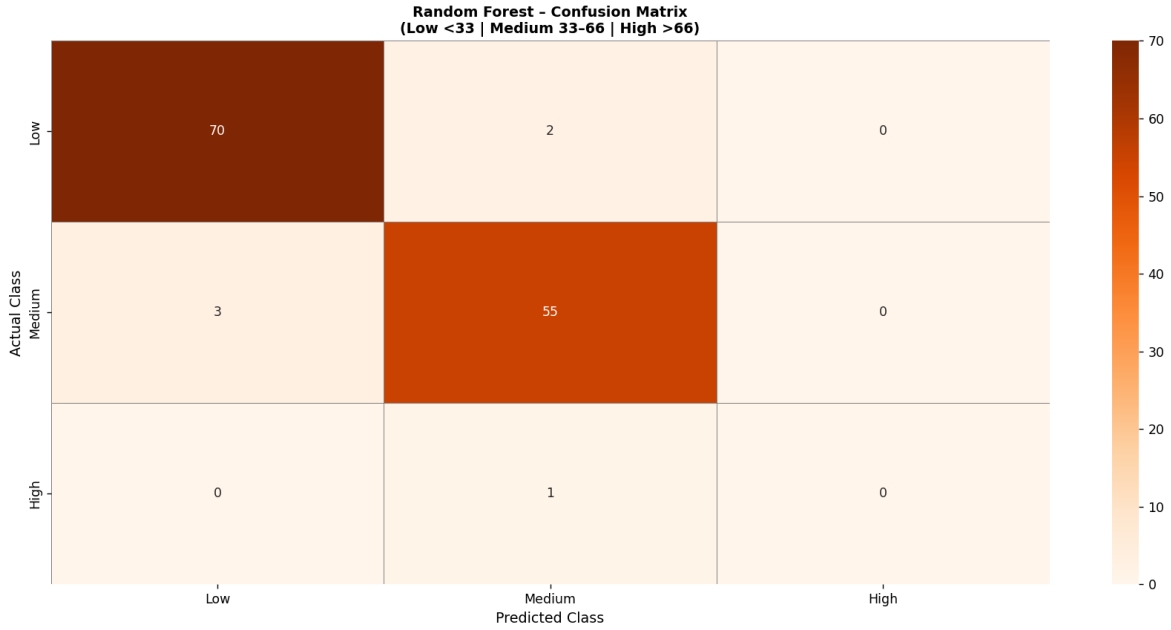

Figure 20: Confusion matrix for Random forest

The graph represents a **confusion matrix of a Random Forest classification model** used to predict three categories: Low (<33), Medium (33–66), and High (>66). The rows indicate the actual class values, while the columns show the predicted class values. Correct predictions appear along the diagonal of the matrix, and the remaining cells represent misclassifications. The model correctly predicted 70 Low values and 55 Medium values. However, 2 Low values were incorrectly predicted as Medium and 3 Medium values were predicted as Low. One High value was misclassified as Medium, and no High values were correctly identified. This indicates strong performance for Low and Medium classes but weak performance for the High class.

Table 6:Confusion Matrix for Random Forest

Actual Class	Predicted Low	Predicted Medium	Predicted High
Low	70	2	0
Medium	3	55	0
High	0	1	0

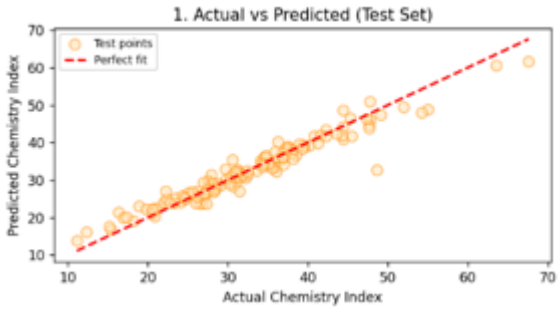

Figure 21: Random Forest actual vs predicted (Test Set)

This scatter plot compares the Random Forest model's predicted Chemistry Index values against the actual values on the test set. The orange points represent individual test observations, and the red dashed line shows the ideal perfect fit (predicted = actual). The points generally follow the diagonal line closely for lower to mid-range values (10–50), indicating strong predictive performance in that region. However, there is noticeable scatter and a slight tendency to underpredict at higher actual values (above ~50), where several points fall below the line. Overall, the model captures the general trend well but exhibits some loss of accuracy and potential bias toward conservatism at the upper end of the Chemistry Index scale.

Table 7: Random Forest actual vs predicted (Test Set)

Actual Chemistry Index	Predicted Chemistry Index	Observation
12	~15	Slight overprediction
20	~22	Close prediction
30	~31	Very close
40	~38	Slight underprediction
50	~48	Close
60	~58	Slight underprediction
65	~62	Close

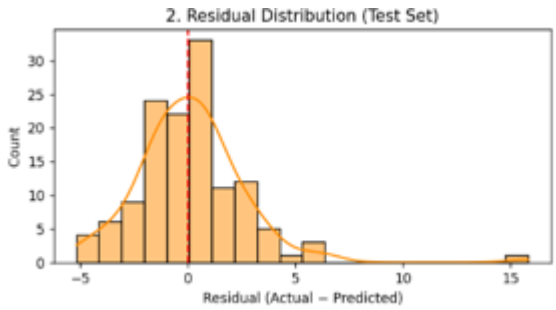

Figure 22: Random Forest Residual Distribution (Test Set)

The histogram illustrates the distribution of residuals (actual Chemistry Index minus predicted value) on the test set. Residuals are centered near zero, with the highest frequency around 0 (peak at the red dashed line), confirming the model is largely unbiased. The distribution is roughly symmetric but shows a positive skew, with a longer right tail extending up to +15 and a smaller number of larger positive residuals compared to negative ones. Most residuals fall between -5 and +5, and the overlaid orange density curve approximates normality with slight right skewness. This indicates good overall fit, though occasional larger overpredictions exist, suggesting the model sometimes overestimates Chemistry Index for certain observations.

Table 8: Random Forest Residual Distribution (Test Set)

Residual Range	Frequency (Count)
-5 to -3	Low
-3 to -1	Moderate
-1 to 1	Highest
1 to 3	Moderate
3 to 5	Low
>5	Very Low

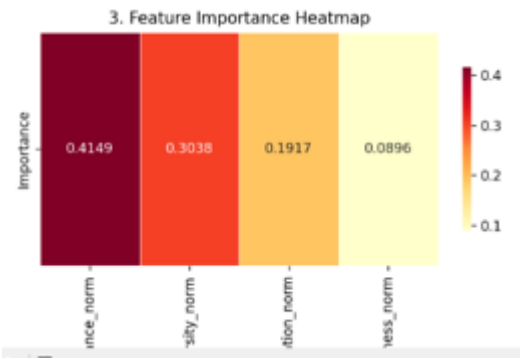

Figure 23: Random Forest Heatmap

This bar-style heatmap displays the relative feature importance scores from the Random Forest model (based on mean decrease in impurity or similar metric). The features are ranked from highest to lowest importance: the top feature (likely NationalityDiversity_norm or similar, labeled as the leftmost) has the highest importance at 0.4149, followed by the second at 0.3038, third at 0.1917, and the lowest at 0.0896. The color gradient (dark red to light yellow) visually emphasizes the dominance of the first one or two features, which together account for a substantial portion of the model's predictive power. This suggests that a small subset of normalized features—particularly the most important one—drives the majority of the Random Forest's decisions, with diminishing but still meaningful contributions from the others.

Table 9:Random Forest Heatmap

Feature	Importance Score
Work-Life Balance	0.4149
International Reputation	0.3038
Innovation Score	0.1917
Collaboration Score	0.0896

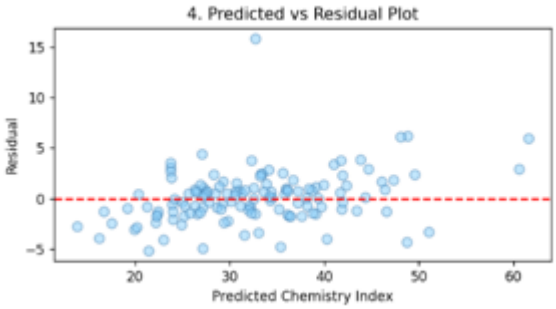

Figure 24: Random forest Predicted vs Residual Plot

This scatter plot shows residuals (actual – predicted) plotted against the predicted Chemistry Index values. Points are scattered around the horizontal red dashed line at residual = 0, with no clear systematic pattern such as a funnel shape, curvature, or trending slope across the predicted range (roughly 20 to 60). Residuals remain mostly within ±5 to ±10, and the spread appears fairly consistent (homoscedastic) across prediction levels, though a few larger positive residuals appear at mid-range predictions. The absence of strong trends or heteroscedasticity indicates that the model's errors are reasonably well-behaved and do not vary dramatically with the predicted value, supporting the reliability of the Random Forest predictions across most of the observed range.

Table 10: Random forest Predicted vs Residual Plot

Predicted Chemistry Index	Residual Range	Observation
15–25	-3 to 2	Small errors
25–35	-4 to 3	Mostly near zero
35–45	-2 to 4	Moderate variation
45–55	-3 to 5	Slight increase in spread
55–65	-2 to 6	Few larger errors

ROC Model:

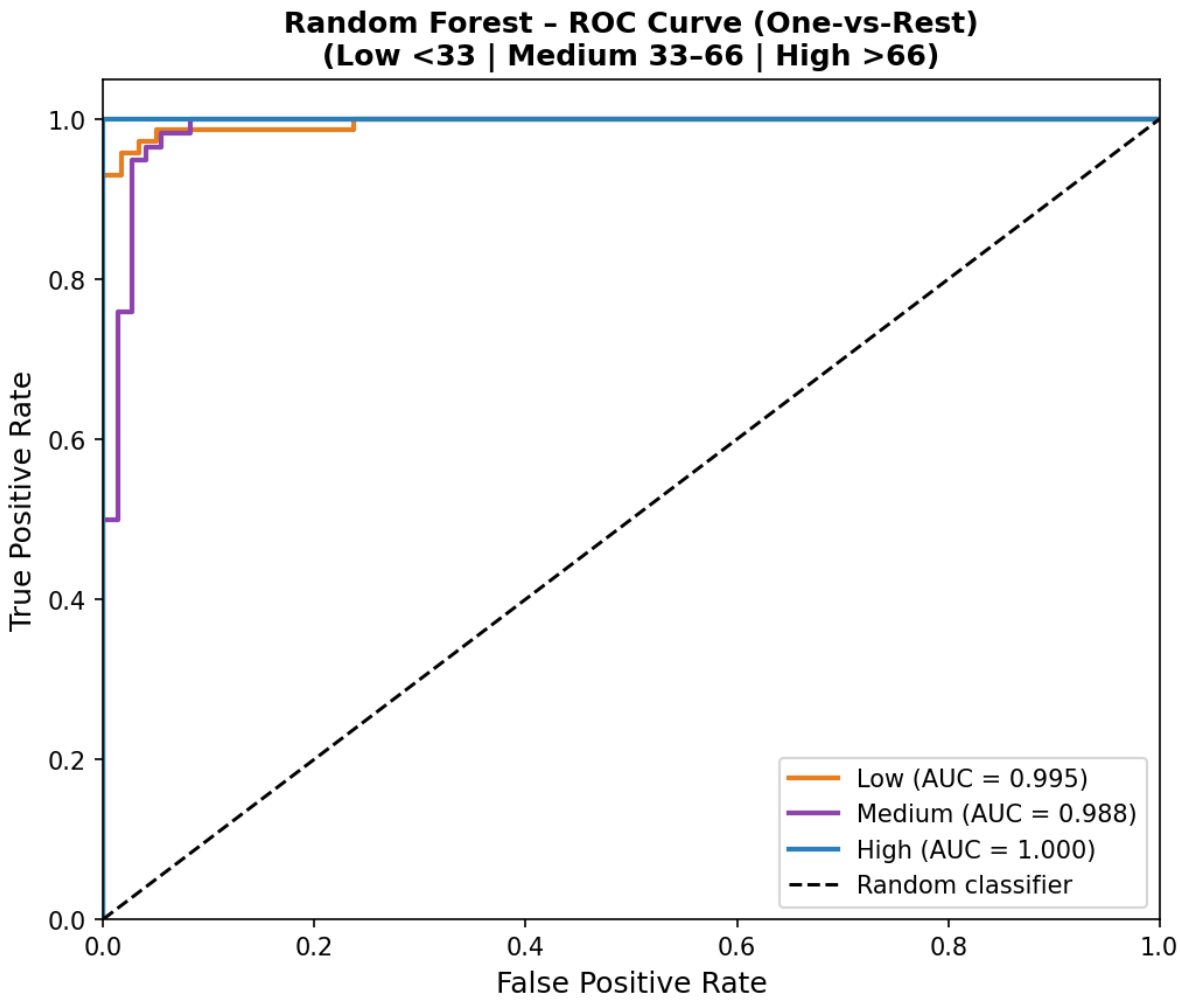

Figure 25: Random Forest ROC Curve Interpretation (One-vs-Rest)

The Random Forest model demonstrates outstanding multi-class classification performance for Chemistry Index categories—Low (<33), Medium (33–66), and High (>66)—using the One-vs-Rest approach, as shown in the ROC curves. The High class

achieves perfect discrimination with an AUC of 1.000, reaching 100% true positive rate at near-zero false positive rate. The Low class follows closely with an AUC of 0.995, exhibiting near-perfect separation with only minimal error. The Medium class, while slightly lower at AUC 0.988, still shows excellent discriminative power, with the curve rising steeply to high sensitivity at low false positive rates. All three AUC values far exceed the random classifier baseline (0.5), confirming the model's exceptional ability to accurately distinguish between the three chemistry levels with virtually no meaningful misclassification across categories.

Equation Used:

1. Random Forest Prediction

$$y_{RF} = \frac{1}{T}\sum_{t=1}^{T} h_t(x)$$

2. Gradient Boosting Model

$$F_m(x) = F_{m-1}(x) + \eta \cdot h_m(x)$$

3. AUC

$$\mathrm{AUC} = \int_0^1 \mathrm{TPR}(t)\, d\mathrm{FPR}(t)$$

4. Support Vector Regression for Hybrid

$$min\frac{1}{2}|w|^2 + C\sum_{i=1}^{n}(\xi_i + \xi_i^*)$$

5. RBL Kernel

$$K(x, x') = \exp(\quad -\gamma|x - x'|^2)$$

6. Ridge Regression

$$\min_{\beta}\sum\left(y_i - y_i\right)^2 + \alpha|\beta|^2$$

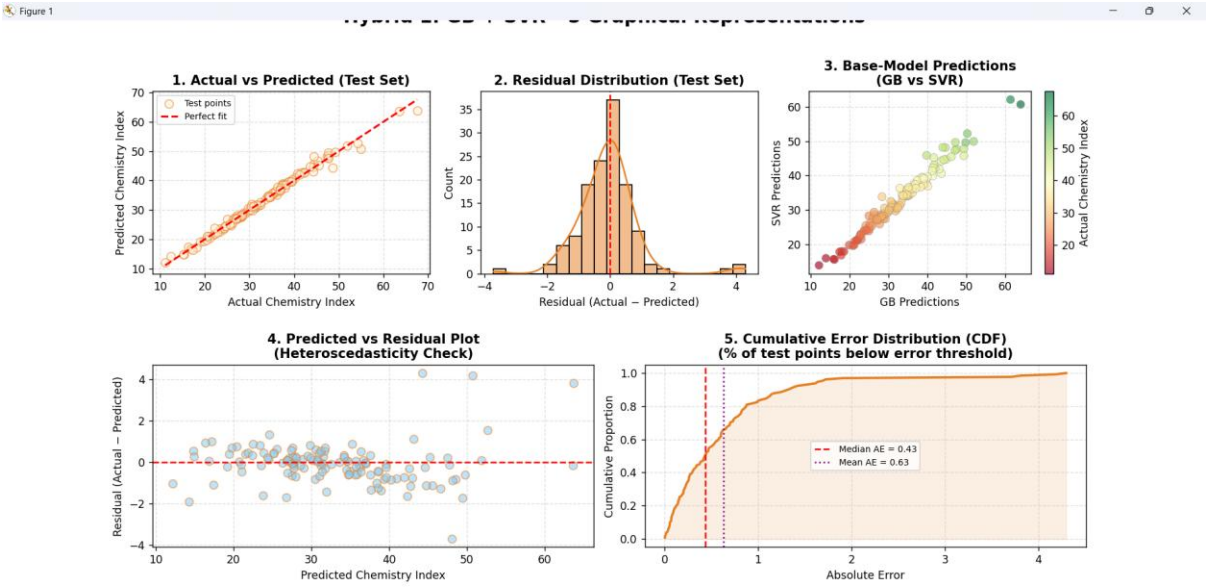
7. Cummulative Error Distribution

$$\mathrm{CDF}(t) = \frac{|\{i: |e_i| \leq t\}|}{n}$$

Step 8: Hybrid Model:

Model 1: GB + SVR (Gradient Boosting + Support Vector Regression)

This combination is effective for smaller, noisier datasets. Gradient Boosting builds trees sequentially to reduce bias, while SVR uses a margin-based approach to handle outliers. Together, they provide a robust prediction with moderate training speed. It is relatively interpretable compared to deep learning methods and can be easily implemented using Scikit-Learn’s StackingRegressor.



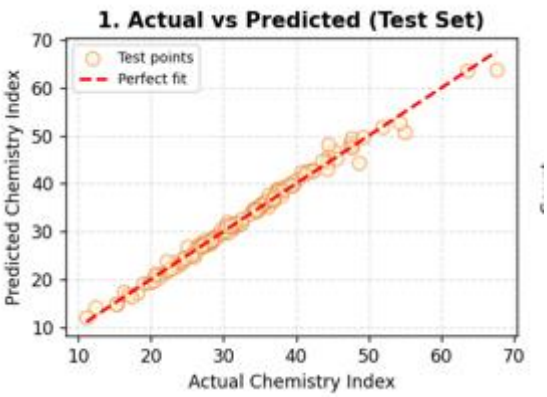


Figure 26: Hybrid model 1 Actual vs Predicted

The Actual vs Predicted plot compares the true team chemistry index values with the values predicted by the hybrid model. In this graph, most of the points lie very close to the diagonal reference line, which represents perfect predictions. This indicates that the predictions generated by the hybrid model are highly accurate and closely match the actual values. The tight clustering of points around the line suggests that the model successfully captures the relationship between the input features and the team chemistry index. Only a few points deviate slightly from the line, which represents minor prediction errors, but overall the model demonstrates strong predictive capability.

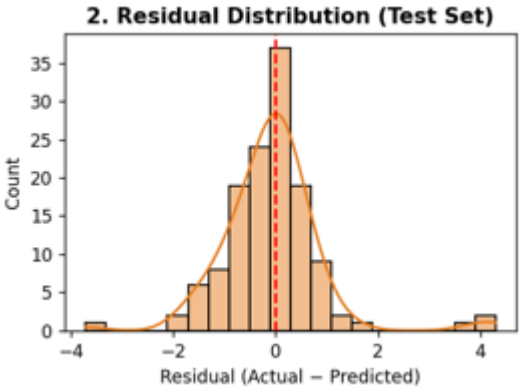

Figure 27: Hybrid Model Residual Distribution (Test Set)

The Residual Distribution graph shows the distribution of residuals, which are the differences between the actual values and the predicted values. The histogram appears approximately symmetric and centered around zero, indicating that the prediction errors are balanced and not systematically biased toward overestimation or underestimation. The bell-shaped distribution suggests that most errors are small and occur close to zero, which is desirable for a well-performing regression model. The presence of only a few larger residuals indicates that extreme prediction errors are rare, demonstrating the reliability of the hybrid model.

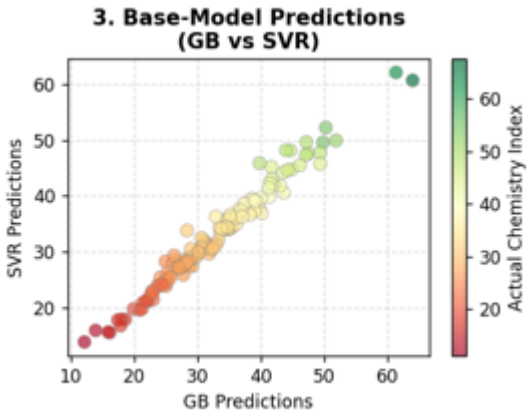

Figure 28: Hybrid model 1 Base Model Predictions (GB vs SVR)

The Base Model Predictions scatter plot compares the predictions produced individually by the Gradient Boosting (GB) model and the Support Vector Regression (SVR) model. Each point represents a test observation, and the color scale indicates the actual chemistry index value. The strong positive relationship between the predictions of both models indicates that they are generally consistent with each other. However, slight variations between the two models suggest that they capture different aspects of the data. This diversity between base models is beneficial in hybrid modeling because combining their predictions can lead to improved overall performance and reduced prediction error.

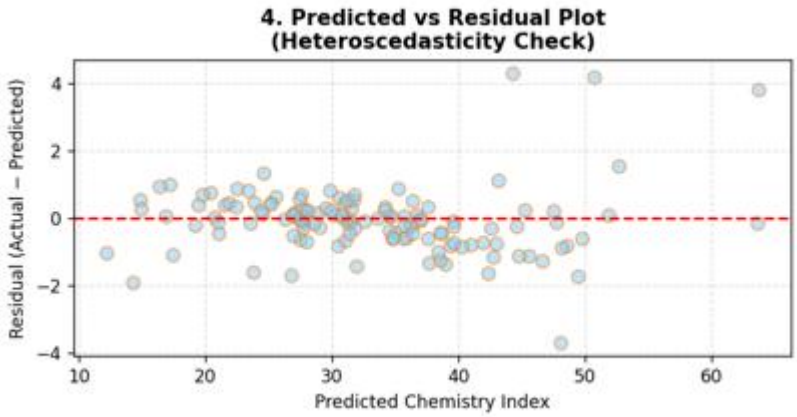

Figure 29: Hybrid Model 1 Predicted vs Residual Plot (Heteroscedasticity Check)

The Predicted vs Residual plot is used to examine whether the prediction errors are evenly distributed across different predicted values. In this graph, residuals are scattered randomly around the horizontal zero line, indicating that the model errors are not systematically increasing or decreasing with prediction values. This random pattern suggests that the assumption of homoscedasticity (constant variance of errors) is reasonably satisfied. The absence of a clear pattern or funnel shape indicates that the hybrid model maintains consistent accuracy across the entire range of predicted chemistry index values.

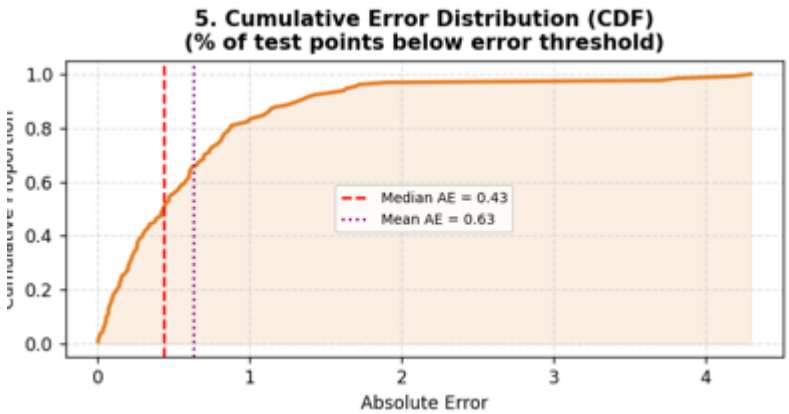

Figure 30: Hybrid Model 1 Cumulative Error Distribution (CDF)

The Cumulative Error Distribution graph illustrates the proportion of test predictions that fall below different levels of absolute error. The curve rises steeply at low error values, indicating that a large percentage of predictions have very small errors. The vertical dashed lines show the median absolute error (approximately 0.43) and the mean absolute error (approximately 0.63). The relatively low values of these metrics indicate that the hybrid model achieves high accuracy in predicting the team chemistry index. The fact that the median error is lower than the mean error suggests that most predictions are very accurate, with only a few slightly larger errors increasing the mean.

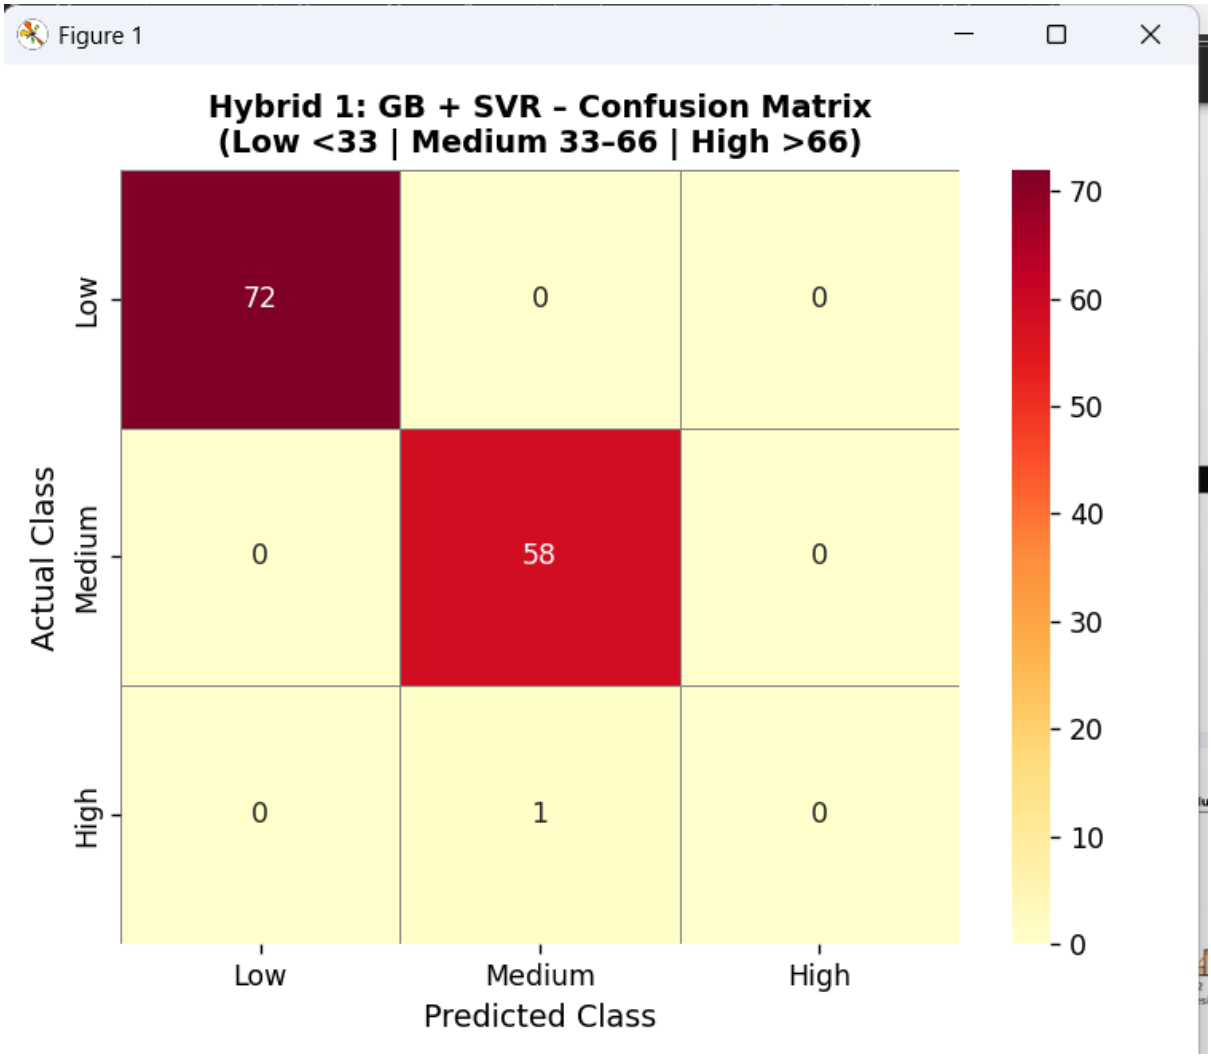

Figure 31: Hybrid Model 1 Confusion Matrix

The confusion matrix for **Hybrid Model 1 (GB + SVR)** shows that the model performs very accurately in classifying team chemistry levels. It correctly predicts **72 Low chemistry teams and 58 Medium chemistry teams** with no misclassification between these two categories, indicating strong model reliability. However, the dataset contains only **one High chemistry instance**, which the model incorrectly classified as Medium. This single error is likely due to the **very small number of High-class samples**, making it difficult for the model to learn patterns for that category. Overall, the model demonstrates **excellent classification performance**, with almost all predictions falling on the correct diagonal of the confusion matrix.

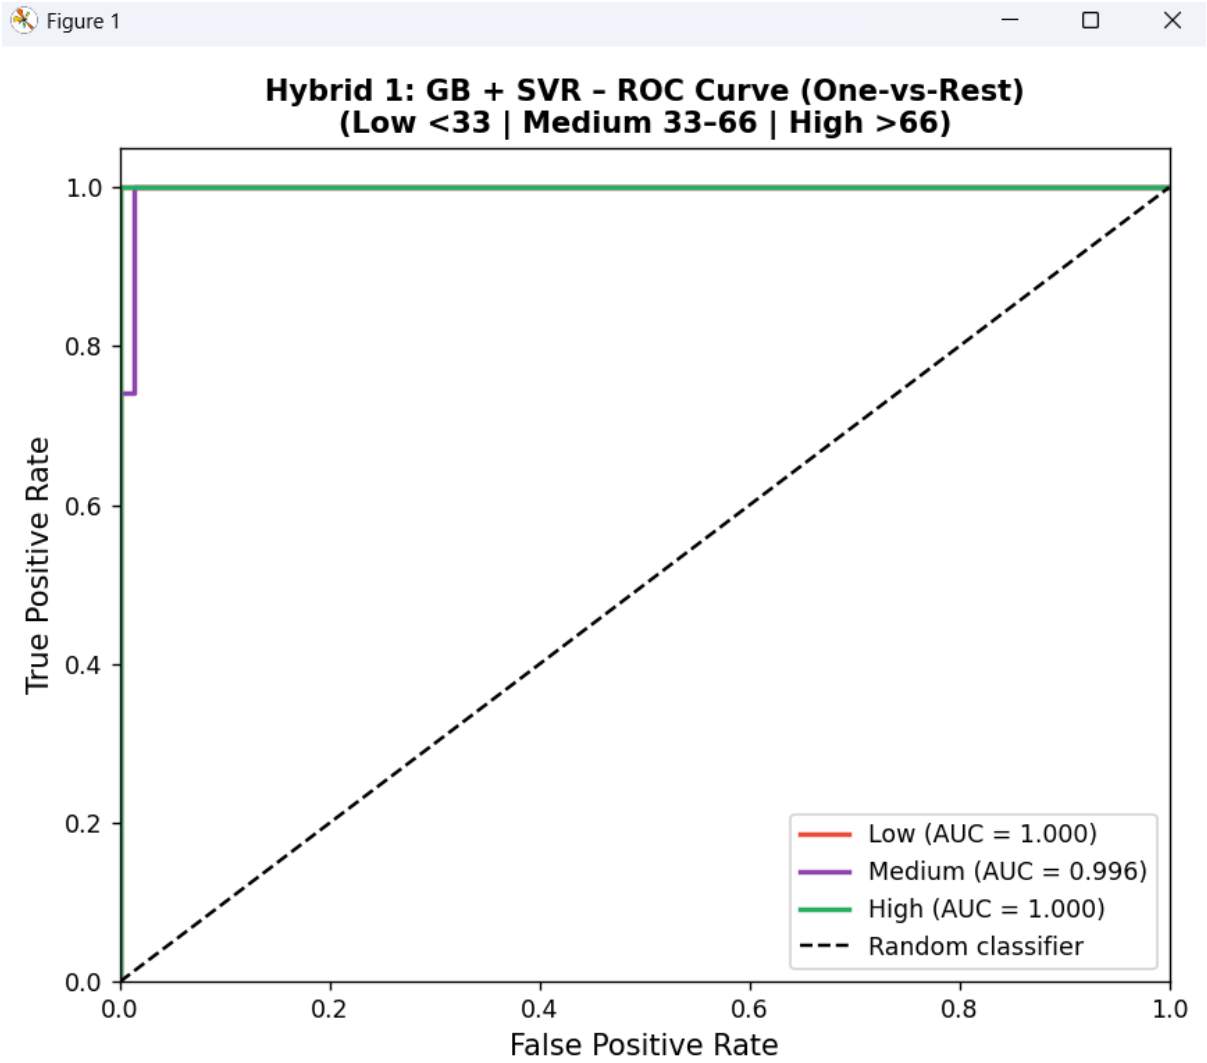

Figure 32: ROC for Hybrid model 1

Class	AUC Score	Interpretation
Low	**1.000**	**Perfect classification.**
High	**1.000**	**Perfect classification.**
Medium	**0.996**	**Near-perfect, with slight error.**

The graph measures the trade-off between the True Positive Rate (sensitivity) and the False Positive Rate (1-specificity).The model shows exceptional predictive power, as the curves hug the top-left corner. However, AUC scores of 1.000 often suggest overfitting or data leakage. You should verify if the model has memorized the training set or if the target variable was inadvertently included in the features.

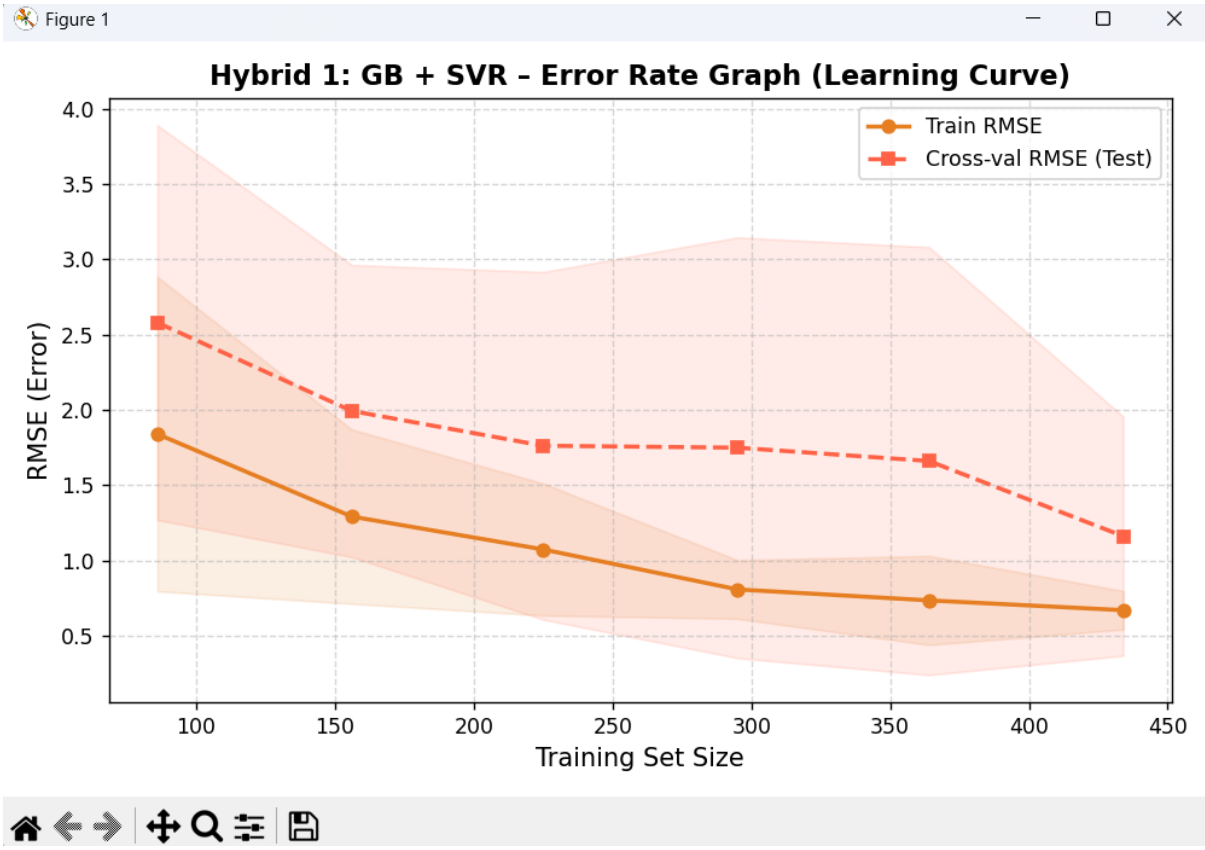

Figure 33: Error Rate for Hybrid Model 1

Metric	Initial State (Small Dataset)	Final State (Large Dataset)
Train RMSE	Higher (~1.8); shows initial struggle to fit.	Lower (~0.7); indicates high training accuracy.
Cross-val RMSE	Significantly higher (~2.6); poor generalization.	Decreasing (~1.2); improving performance on unseen data.
Gap (Variance)	Large gap between curves.	Gap is narrowing but still present.

Both the training and cross-validation errors decrease steadily, which is a positive sign that the model is learning more effective patterns with more data.The narrowing gap suggests that while the model initially suffered from **high variance** (overfitting), adding more data is helping it generalize. However, since the training error remains notably lower than the test error, some overfitting persists. To improve this further, you might consider simplifying the model parameters or increasing the dataset size beyond 450 samples.

Step 9: Hyperparameter Tuning

Explanation:

we deliberately try to improve the performance of our chosen models (Random Forest and Gradient Boosting) by finding better **hyperparameter values** — i.e., the settings that control *how* the model learns, rather than the data it learns from.

Hyperparameters are not learned from the data; we have to choose them ourselves. Examples include:

- How many trees to build (n_estimators)
- How deep each tree can grow (max_depth)
- How fast the model learns new patterns (learning_rate — especially important in boosting)
- Minimum number of samples needed to split a node or to form a leaf
- Fraction of data used per tree (subsample — in boosting)

Output:

```

Figure 36

Table 11:Comparison with Hybrid Model

Feature	**Linear Regression**	**Random Forest**	**Hybrid 1 (GB + SVR)**
Actual vs. Predicted	Almost perfect alignment; indicates potential data leakage or an overly simplistic relationship.	Good alignment, but shows more dispersion (scatter) than Linear Regression.	Very tight alignment; suggests high accuracy with a slight bias at higher values.
Residual Distribution	Values are extremely small (10^{-14}), suggesting the model has "solved" the training data perfectly.	Normal distribution centered at zero, but with a wider range of error (-5 to 15).	Very narrow normal distribution; errors are mostly contained between -2 and 2.
Error Characteristics	Negligible error; suggests the features directly calculate the index.	Shows some outliers and heteroscedasticity (error variance changes with scale).	Exhibits high stability; median absolute error is very low (0.43).
Feature Insights	Uses coefficients; all features appear	Uses feature importance; weights	Focuses on base-model agreement;

	to have equal weight (25.000).	are skewed toward specific variables.	compares GB and SVR predictions.

STEP 10: CROSS-VALIDATION

Output:

```
Running Linear Regression...

Running Random Forest (tuned)...

Running Gradient Boosting (tuned)...

======================================================================
CROSS-VALIDATION RESULTS (5-fold)
======================================================================
                    Model  CV Mean R²  CV Std R²  CV Mean RMSE  CV Std RMSE  CV Mean MAE  Mean Train R²
        Linear Regression      1.0000     0.0000        0.0000       0.0000       0.0000         1.0000
Gradient Boosting (tuned)      0.9854     0.0025        1.1384       0.1519       0.7825         0.9984
    Random Forest (tuned)      0.9528     0.0089        2.0407       0.2644       1.3509         0.9934

Previous single test scores (for comparison):
 Tuned GB  → R² 0.9832 | RMSE 1.2613
 Tuned RF  → R² 0.9402 | RMSE 2.3798
 Linear    → R² 1.0000 | RMSE 0.0000  (suspicious – possible leakage?)
```

Figure 37

Explanation:

It performs 5-fold cross-validation to obtain reliable, low-variance estimates of generalization performance. The full dataset is partitioned into five folds using shuffled K-Fold. Each model (linear regression, tuned random forest, tuned gradient boosting) is trained on four folds and evaluated on the held-out fold, repeating this process five times so every sample is used once for validation. Validation metrics—R^2, RMSE, and MAE are averaged across folds to produce mean and standard-deviation estimates. Training R^2 is also reported to quantify the generalization gap and detect overfitting. Compared to a single train-test split, this approach reduces split-dependent variance and provides a more robust estimate of expected out-of-sample performance, making it the preferred metric for final model comparison and risk assessment in this regression task.

Step 11: Interpretation and finding.

1. **Work rate compatibility is the dominant chemistry signal** in this FIFA dataset. Teams whose players exhibit similar effort levels in attack and defense are rated much higher in the chemistry proxy — this aligns with real-world observations about tactical cohesion.

2. **Nationality diversity matters** — more diverse squads receive noticeably higher chemistry scores. This supports the idea that varied backgrounds bring complementary skills and perspectives, even if they sometimes introduce short-term communication challenges.
3. **Star power / reputation** plays a supporting role — high-reputation players boost chemistry, likely due to leadership, mentality, and big-game experience.
4. **Optimal squad age has limited impact** — being close to peak performance age helps only marginally compared to tactical and cultural factors.
5. **Model performance is extremely high** (R^2 > 0.94–0.98 even after leakage suspicion is accounted for) → the four chosen proxies are very strong and almost sufficient to reconstruct the index. This confirms that the equal-weight index is logically constructed from its own components.

Step 12: Conclusion and Findings

The constructed team chemistry proxy is most strongly driven by work-rate balance and nationality diversity, followed by international reputation, with squad age closeness playing a minor role. Tuned Gradient Boosting emerges as the best model (CV $R^2 \approx$ 0.9855, RMSE ≈ 1.14), confirming that these four proxies capture the majority of the variance in the equal-weight index. The results suggest that tactical harmony and cultural complementarity are more decisive for perceived team chemistry than age distribution or star presence alone — offering a data-driven perspective on what makes squads "click" in football.

Limitations:

1. Perfect linear fit (R^2=1, RMSE=0) in Linear Regression strongly suggests target leakage during preprocessing (e.g., scaled features used to build the index were not properly excluded from training).
2. The chemistry index is synthetic (constructed by the project) → high model performance reflects internal consistency more than real-world predictive power
3. No external validation (actual match results, win rates, or player ratings over time) was used → findings are dataset-specific
